## Abstract

The objective of this study was to evaluate the intramammary distribution of MRI-detected mass and focus lesions that were difficult to identify with conventional B-mode ultrasound (US) alone. Consecutive patients with lesions detected with MRI but not second-look conventional B-mode US were enrolled between May 2015 and June 2023. Following an additional supine MRI examination, we performed third-look US using real-time virtual sonography (RVS), an MRI/US image fusion technique. We divided the distribution of MRI-detected mammary gland lesions as follows: center of the mammary gland versus other (superficial fascia, deep fascia, and atrophic mammary gland). We were able to detect 27 (84%) of 32 MRI-detected lesions using third-look US with RVS. Of these 27 lesions, 5 (19%) were in the center of the mammary gland and 22 (81%) were located in other areas. We were able to biopsy all 27 lesions; 8 (30%) were malignant and 19 (70%) were benign. Histopathologically, three malignant lesions were invasive ductal carcinoma (IDC; luminal A), one was IDC (luminal B), and four were ductal carcinoma in situ (low-grade). Malignant lesions were found in all areas. During this study period, 132 MRI-detected lesions were identified and 43 (33%) were located in the center of the mammary gland and 87 (64%) were in other areas. Also, we were able to detect 105 of 137 MRI-detected lesions by second-look conventional-B mode US and 38 (36%) were located in the center of the mammary gland and 67 (64%) were in other areas. In this study, 81% of the lesions identified using third-look US with RVS and 64% lesions detected by second-look conventional-B mode US were located outside the center of the mammary gland. We consider that adequate attention should be paid to the whole mammary gland when we perform third-look US using MRI/US fusion technique.

## Background

Magnetic resonance imaging (MRI) of the breast is a useful tool for detecting breast cancer. MRI is increasingly used to assess symptoms, screen women at high risk for breast cancer, stage known breast cancers, and screen the contralateral breast in patients with newly diagnosed breast cancer [1, 2]. Several authors have questioned the utility of preoperative MRI, given the possibility of overdiagnosis or false-positives [3, 4]. However, others have reported that MRI can reliably predict tumor progression, especially in very dense breasts [5].

The specificity and moderate positive predictive value of MRI can limit its effectiveness. A recent meta-analysis about using preoperative MRI to detect multifocal or multicentric cancers in the ipsilateral breast showed that the rate of additional cancer foci being detected ranged from 6 to 34%; the median was 16% and the positive predictive value was 66% [6]. Thus, breast biopsy is necessary in order to definitively diagnose suspicious lesions, especially in MRI-detected lesions that are not detected on initial mammography and ultrasound (US). When lesions detected with MRI are also detected with second-look US, US-guided biopsy is recommended.

Second-look US has detection rates that vary substantially [7–11]. Moreover, it is difficult to identify all lesions because examination success depends on the sonographer's experience and skill. Furthermore, lesion characterization with breast US has not reproducible among examiners, which remains a clinical challenge.

MRI-guided biopsy has been developed over the past several years to help diagnose conventional B-mode-ocult breast lesions detected with MRI. Compared with other modalities, MRI-guided biopsies are less accurate [12–14]. Moreover, target sampling is more difficult after MRI-guided biopsy than after biopsy with ultrasound or stereotactic guidance. Radiopathologic correlation after MRI-guided biopsy is particularly challenging when MRI lesions only enhance in vivo and their presence cannot be confirmed in the biopsy specimen, even when biopsy markers have been appropriately placed [12].

Real-time virtual sonography (RVS) is an MRI/US image fusion technique introduced in 2005. RVS combines real-time sonography with MRI, allowing for the display of images from both imaging modalities on the same monitor. During sonography, the RVS system identifies the probe's position and movement. It simultaneously reconstructs an equivalent MRI image from previously imported volume data. If a lesion that was initially detected with prone MRI cannot be identified during second-look conventional B-mode US, we add supine MRI and perform second-look US using RVS (third-look US using RVS in this study). Regarding breast deformation, tumor displacement during MRI results from

discrepancies between positions during supine versus prone examination [8, 15–17].

Satake et al. reported that tumor displacement in the breast during MRI due to prone versus supine positioning varies by tumor location. It is most common in the inner lower quadrant [18]. Carbonaro et al. reported that lesion-to-nipple distance might be the most reliable measure for second-look breast US [19]. However, few studies have examined the intramammary distribution of MRI-detected lesions in detail by dividing them into zones with third-look US using RVS. In the report by Nakano et al., supine MRI was performed first and prone MRI was not mandatory [16]. In this study, prone MRI was performed first, and when MRI-detected lesions were detected, supine MRI was added and third-look US using RVS was performed. The protocol of this study was different from that of Nakano et al. [16] in this regard, and we decided to validate the distribution of MRI-detected lesions with this protocol. The objective of this study was to evaluate the intramammary distribution of MRI-detected mass and focus lesions that were difficult to identify with conventional B-mode US alone.

## Methods

### Patients and lesions

This study was approved by the institutional review board of Aichi Medical University Hospital (No. 2022–125). The need for written informed consent was waived for this research study. Consecutive patients with one or more MRI-detected lesions that were not identified with second-look conventional B-mode US between May 2015 and June 2023 were enrolled in this study. Third-look US using RVS was performed to identify these lesions. Non-mass enhancement (NME) was excluded from this study because of the difficulty in objectively assessing them. US-guided biopsy was performed for MRI-detected lesions detected with RVS; additional excisional biopsy was performed if necessary.

### Prone MRI

Prone MRI was used for preoperative assessment or to evaluate abnormal findings further. A dedicated double-breast coil was used with a 1.5-T scanner (Magnetom, Siemens Medical Systems, Erlangen, Germany) [20].

### Second-look conventional B-mode US

After prone MRI, a 13-MHz linear array probe (HI VISION Ascendus, ARIETTA 850; FUJIFILM Health care Corporation, Japan) was used for second-look conventional B-mode US with the patient in the supine and arm-up position [20]. It was performed by experienced surgeons routinely involved in breast cancer treatment regardless of the experiences of third-look US using RVS.

### Supine MRI

When a lesion initially detected with prone MRI was not identified with second-look conventional B-mode US, supine MRI was added to acquire the data necessary for US using RVS. Supine MRI with a 1.5-T scanner (Magnetom, Siemens Medical Systems) was performed with the arm raised [20]. A flexible body surface coil was used to achieve the same position as that used in US [15, 20]. Acquisition was performed as described previously. We evaluated the lesion size, type (focus, mass, or NME), shape (oval, round, irregular), margin (circumscribed, irregular, spiculated), internal enhancement (homogeneous, heterogeneous, rim enhancement, dark internal septations) and kinetic curve assessment according to Breast Imaging Reporting and Data System (BI-RADS) criteria of prone MRI [21].

### Third-look US using RVS

Third-look US using RVS was performed in the supine and arm-up position [8, 15–17, 22, 23] (Fig. 1a, b). The RVS system consisted of an US scanner, magnetic field generator, magnetic sensor, and workstation with built-in RVS software (FUJIFILM Health care Corporation). The process began with the transfer of breast MRI data, in the Digital Imaging and Communications in Medicine (DICOM) format, to the workstation. Subsequently, the magnetic sensor detected the position and probe motion during the examination by sensing a magnetic field. Next, the 3D position of the probe was transmitted to the workstation, which computed the information regarding the position and displayed the MRI-multi-planar reconstruction image equivalent to the US image on the workstation

monitor. The nipple on the side being examined was used as the reference point for synchronizing the MRI and US images. Correction was made during the examination by checking the location of the lesion compared to the blood vessels, fat, ligaments and mammary glands [9].

### RVS-guided biopsy

When MRI-detected lesions were identified with RVS, US-guided biopsy was performed. Core needle biopsy (CNB) was performed with a 16-gauge spring-loaded automatic core needle (Monopty; C.R. Bard, Covington, GA, USA) [20]. If the result of CNB was high-risk atypical ductal hyperplasia, preoperative RVS-guided marking and excisional biopsy were performed; the final histopathological classification was based on this biopsy sample [15]. This examination is contraindicated for patients with pacemakers.

### Pathological criteria for invasive ductal carcinoma (IDC) and other special types

IDC subtype was determined according to hormonal receptor (HR) status, Ki-67 status, and HER-2 status [22]. Immunohistochemical staining was performed in the same way even for tissue types other than IDC.

### Pathological criteria for ductal carcinoma in situ (DCIS)

DCIS subtype was classified as low-, intermediate-, or high-grade based on the features of the nuclei of the neoplastic cells [24].

**Fig. 1** RVS system equipment in the outpatient clinic (a). When performing RVS, the attachment containing the magnetic sensor is fitted into the handle of the probe (b). RVS: real-time virtual sonography

**Intramammary distribution of MRI-detected lesions**

We divided the distribution of MRI-detected mammary gland lesions located from the skin to the pectoralis major muscle into four regions: adjacent to the superficial mammary fascia (s area), adjacent to the deep mammary fascia (d area), center of the mammary gland (c area), and atrophic mammary gland (a area) (Fig. 2) [16].

**Results**

This study included 32 women (median age, 57 years; range, 41–73) with 32 lesions (22 mass lesions and 10 focus lesions) detected with MRI but not with second-look conventional B-mode US. Third-look US using RVS was able to detect 27 (84%) of these 32 lesions (19 [86%] of 22 mass lesions and 8 [80%] of 10 focus lesions). The 5 MRI-detected lesions that could not be identified were followed-up annually with third-look US using RVS. No changes were observed in these lesions in one years. Table 1 shows the MRI characteristics of the MRI-detected lesions. Table 2 shows the MRI and US characteristics of the benign and malignant lesions.

The intramammary distribution of benign and malignant lesions is shown in Table 3. Of these, 16 were located around the mammary fascia (9 [33%] in s area and 7 [26%] in d area), 5 (19%) in c area, and 6 (22%) in

a area. Of the 21 lesions not located in a area, where the mammary gland was atrophic and the landmarks were not obvious, 16 (76%) were located around the mammary fascia, i.e., in the marginal part of the mammary gland. Figures 3, 4, 5 and 6 show cases located in each of the four areas.

During this study period, we performed 1426 breast MRI and identified 215 MRI-detected lesions (mass in 119, NME in 76, focus in 18). Regarding MRI-detected mass and focus lesions, we were able to detect 105 lesions by second-look conventional B-mode US and 27 lesions using third-look US using RVS. Second-look conventional B-mode US detected 97 mass lesions and 8 focus lesions. Table 4 shows the distribution of MRI-detected mass and focus lesions. In these MRI-detected mass and focus lesions, 78 (57%) were located around the mammary fascia (42 [31%] were located in s area and 36 [26%] in d area), 46 (34%) in c area and 13 (9%) in a area. In the MRI-detected mass and focus lesions detected by second-look conventional B-mode US, 60 (57%) were located around the mammary fascia (32 [30%] were located in s area and 28 lesions [27%] in d area), 38 lesions (36%) in c area and 7 lesions (7%) in a area. In the MRI-detected mass and focus lesions which couldn't be detected were located in 1 lesion (20%) was

located in s area, 3 lesions (60%) in c area and 1 lesion (20%) in d area.

We were able to perform RVS-guided biopsy of all 27 lesions detected by third-look US using RVS. CNB and excisional biopsy were performed, respectively, in 17 (63%) and 10 (37%) of the 27 lesions overall. This corresponded to 13 (68%) and 6 (32%) of the 19 mass lesions and 4 (50%) and 4 (50%) of the 8 focus lesions, respectively. Of the 27 lesions, 8 (30%) were malignant, which consisted of 5 of 19 (26%) mass lesions and 3 of 8 (38%) focus lesions.

The histopathological results of the malignant lesions were IDC (luminal A) in three lesions (all focus lesions), IDC (luminal B) in one mass lesion, and DCIS (low-grade) in four (all mass lesions). The histopathological results of benign lesions were mastopathy in 3, intraductal papilloma in 2, atypical ductal hyperplasia in 1, atypical lobular hyperplasia and hemangioma in 1, and other in 12. Malignant lesions were located in all areas:

around the mammary fascia in 63% (s area in 3 [38%] lesions, d area in 2 [25%] lesions), c area in 1 (13%) lesion, and a area in 2 (25%) lesions.

## Discussion

In this study, 27 (84%) of 32 MRI-detected mass and focus lesions were able to be detected by third-look US using RVS. Of these 27 lesions, 16 were around the mammary fascia (9 [33%] in s area and 7 [26%] in d area), 5 (19%) were in c area, and 6 (22%) were in a area. Malignant lesions were present in all areas. During this study period, 132 MRI-detected mass and focus lesions were identified. In these MRI-detected lesions, 78 (57%) were located around the mammary fascia (42 [31%] were located in s area and 36 [26%] in d area), 46 (34%) in c area and 13 (9%) in a area. In these MRI-detected lesions detected by second-look conventional B-mode US, 60 (57%) were located around the mammary fascia (32 [30%] were located in s area and 28 lesions [27%] in d area), 38 lesions (36%) in c area and 7 lesions (7%) in a area. We consider that adequate attention should be paid to the whole mammary gland when we perform third-look US using MRI/US fusion technique.

While second-look US is inexpensive, radiation-free, and useful for identifying breast lesions detected with MRI, several studies found wide variation in the general detection rate for second-look US, ranging from 59% to 86.8% [7–11]. Other authors have noted that findings on second-look US were subtle, necessitating careful scanning techniques for successful MRI/US correlation [9, 25]. Ultrasound scanning of the breast was performed with special attention to the area of the detected enhancing lesion using MR images as a guide [25]. Furthermore, there is no direct evidence that lesions detected on MRI can be detected and biopsied accurately [8] whereas no special US operator skill or experience is needed to perform RVS. In terms of objectivity and reproducibility, third-look US with MRI/US fusion techniques is considered superior to second-look conventional B-mode US [7, 8, 15–17, 20, 22, 23, 26–30].

Differences in posture between examinations in supine versus prone position cause lesion displacement. Aribal et al. reported that an abbreviated supine sequence following a standard prone dynamic contrast-enhanced diagnostic MRI with one administration of contrast was useful for identifying lesion locations [31]. Breast size and lesion displacement relative to the distance from the sternum or nipple were not correlated [31]. Carbonaro et al. [19] reported that prone MRI resulted in lesion displacement of 30–60 mm in three orthogonal directions relative to supine MRI. Considering that the mean position error for RVS is approximately 12 mm, morphological findings can be directly compared between US and supine MRI

[17]. Moreover, RVS provides accurate information about position even in the absence of landmarks identified with US and MRI. Recent studies have demonstrated the utility of second-look US using RVS that synchronizes supine MRI and US images with respect to the nipple on the side being examined [9, 32]. In addition to the nipple, spatial location of tumor and blood vessels, Cooper's ligament, adipose tissue, and glandular tissue have been reported to be usable as landmark [9]. Also, because the mammary glands are fatty and easily deformed, manipulation of the ultrasound probe and respiratory movement cause misalignment between the ultrasound image and

the MRI-multi-planar reconstruction image. Therefore, the technique to minimize misalignment is to scan the probe gently so as not to compress the breast [17]. We believe these landmarks and techniques enable us to perform biopsies of MRI-detected lesions more accurately.

In this study, the RVS-guided biopsy detection rate for malignant lesions was 30%. According to the BI-RADS classification system [21], the rate with MRI-guided biopsy is 20–50%. Thus, RVS-guided biopsy can be a promising substitute for MRI-guided breast biopsy, but further study is needed.

MRI-guided biopsy is challenging because of various technical issues [33, 34]. First, it is expensive and time-consuming, for patients and radiologists alike. Second, it requires specialized equipment [35]. In contrast, special equipment is not needed for RVS-guided biopsy [9]. Furthermore, the average turnaround time for RVS-guided biopsy is 25 min, which is shorter than the turnaround time for MRI-guided biopsy because the supine breast MRI protocol used in RVS can be shortened [9]. The average time of MRI-guided biopsy was reported about 1 h [36, 37]. The increased use of RVS relative to MRI might be beneficial in terms of time and availability. RVS can also help determine whether an MRI-guided biopsy is absolutely necessary. Performing

**Fig. 3** MRI-detected lesion located in s area. We showed the lesion by an arrow. The patient was a premenopausal woman. Preoperative breast MRI showed a focus lesion with a diameter of 4.0 mm (a). After supine MRI (b), we performed third-look US using RVS. The image b shows a supine MRI MIP image. RVS displayed early-phase MRI-MPR (d), which corresponded to the US image (c). We were able to detect the lesion with RVS and perform excisional biopsy. The diagnosis was IDC and the subtype was luminal A. MIP: maximum intensity projection, MPR: multiplanar reconstruction; IDC: invasive ductal carcinoma

**Fig. 4** MRI-detected lesion located in c area. We showed the lesion by an arrow. The patient was a premenopausal woman. Preoperative breast MRI showed a mass lesion with a diameter of 9.4 mm (a). After supine MRI (b), we performed third-look US using RVS. The image b shows a supine MRI MIP image. RVS displayed the US image (c) and which was corresponded to pre-contrast-phase (d), early-phase (e), and late-phase MRI-MPR (f). We were able to detect the lesion with RVS and perform excisional biopsy. The diagnosis was low-grade DCIS. DCIS: ductal carcinoma in situ

**Fig. 5** MRI-detected lesion located in d area. We showed the lesion by an arrow. The patient was a postmenopausal woman. Preoperative breast MRI showed a mass lesion with a diameter of 5.8 mm (a). After supine MRI (b), we performed third-look US using RVS. The image b shows a supine MRI MIP image. RVS displayed the US image (c) and which was corresponded to pre-contrast-phase (d), early-phase (e), and late-phase MRI-MPR (f). We were able to detect this lesion with RVS and perform CNB. The diagnosis was low-grade DCIS. CNB: core needle biopsy

**Fig. 6** MRI-detected lesion located in a area. We showed the lesion by an arrow. The patient was a premenopausal woman. Preoperative breast MRI showed a mass lesion with a diameter of 5.8 mm (a). After supine MRI (b), we performed third-look US using RVS. The image b shows a supine MRI MIP image. RVS displayed the US image (c) and which corresponded to pre-contrast-phase (d), early-phase (e), and late-phase MRI-MPR (f). We were able to detect this lesion with RVS and performed CNB. The lesion was benign

**Table 4** Intramammary distribution of MRI-detected mass and focus lesions during this study period

	All lesions	Second-look conventional B-mode US correlate	Third-look US using RVS correlate	No second-look conventional B-mode US and third-look US using RVS correlate
s area	42 (31%)	32 (30%)	9 (33%)	1 (20%)
c area	46 (34%)	38 (36%)	5 (19%)	3 (60%)
d area	36 (26%)	28 (27%)	7 (26%)	1 (20%)
a area	13 (9%)	7 (7%)	6 (22%)	0
total	137	105	27	5

third-look US using RVS needs supine MRI. Performing additional supine MRI costs the patient but this study didn't compare the costs of MRI-guided biopsy with those of RVS-guided biopsy.

This study had several limitations. First, it was a retrospective investigation with a relatively small number of patients. Additional prospective studies with more patients are needed. Second, supine breast MRI using a body surface coil is affected by artifacts related to movements during breathing as well as heartbeats. Low coil filling factor leads to poor image quality. Therefore, it is not a firmly established method to diagnose breast cancer. Additional research should be performed to evaluate the accuracy of the method.

**Conclusions**

Third-look US using RVS was able to detect 84% of MRI-detected mass and focus lesions that could not be identified with second-look conventional B-mode US. It was used to evaluate the intramammary distribution of these lesions. 59% of MRI-detected mass or focus lesions detected by third-look US using RVS and 57% of MRI-detected lesions detected by second-look conventional-B mode US were located around the mammary fascia, where the contrast with the surrounding tissue was small. Malignant lesions were present in all areas. MRI-detected lesions were distributed in all areas in the mammary gland. We consider that adequate attention should be paid to the whole mammary gland when we perform

## third-look US using RVS for mass and focus lesions detected by MRI.
